The solar water-splitting protein complex, photosystem II (PSII), catalyzes one of the most energetically demanding reactions in nature by using light energy to drive a catalyst capable of oxidizing water. The water oxidation reaction is catalyzed at the Mn4Ca-oxo cluster in the oxygen-evolving complex (OEC), which cycles through five light-driven S-state intermediates (S0–S4). A detailed mechanism of the reaction remains elusive as it requires knowledge of the delivery and binding of substrate water in the higher S-state intermediates. In this study, we use two-dimensional (2D) hyperfine sublevel correlation spectroscopy, in conjunction with quantum mechanics/molecular mechanics (QM/MM) and density functional theory (DFT), to probe the binding of the substrate analog, methanol, in the S2 state of the D1-N87A variant of PSII from Synechocystis sp. PCC 6803. The results indicate that the size and specificity of the “narrow” channel is altered in D1-N87A PSII, allowing for the binding of deprotonated 13C-labeled methanol at the Mn4(iv) ion of the catalytic cluster in the S2 state. This has important implications on the mechanistic models for water oxidation in PSII.

Introduction

The photosynthetic protein photosystem II (PSII) catalyzes one of the most energetically demanding reactions in nature by using light energy to drive a catalyst capable of oxidizing water.1–3 The light-driven four-electron water oxidation reaction takes place at the catalytic Mn4Ca-oxo cluster in the oxygen-
The core of the cluster is a distorted cubane comprising three Mn (Mn1–Mn3), four O$_2^-$ (O1–O3 and O5), and one Ca$^{2+}$ ion. The fourth ‘dangler’ Mn, Mn4, is connected to the cubane by two $\mu$-O bridges, O4 and O5. The shape of the cluster resembles a distorted chair, with the cubane serving as the base and the Mn4 ion serving as the back of the chair. The distorted shape is important as its flexible nature enables the cluster to undergo structural rearrangements during the catalytic cycle. Additionally, the cluster is coordinated by six carboxylates and one histidine residue, D1-H332, which is coordinated to the Mn1 ion.

It is known that the OEC cycles through five light-driven charge-storage or S-state intermediates (S$_0$–S$_4$) as it accumulates oxidizing equivalents to oxidize water, where S$_4$ is the dark state and S$_0$ is the final transient state that leads to O–O bond formation and oxygen evolution. In recent years, conventional and time-resolved X-ray crystallography, X-ray absorption fine structure (EXAFS), electron paramagnetic resonance (EPR), FTIR and quantum mechanics/molecular mechanics (QM/MM) investigations have provided information on the structure and oxidation states of the metal ions in the OEC during the S-state cycle. The recent X-ray crystal structures have enabled analyses of the location and possible function of water molecules in the OEC. There are four water-derived terminal ligands (W1–W4) coordinated to the Mn$_4$Ca-oxo cluster in the dark-stable S$_1$ state. The binding of these ligands has been studied by several methods, including magnetic resonance, Fourier-
transform infrared spectroscopy (FTIR)\textsuperscript{32,40} and time-resolved membrane-inlet mass spectrometry (TR-MIMS).\textsuperscript{41,42} Based on these studies, it has been concluded that the two substrate waters are delivered to the OEC in the S\textsubscript{1} to S\textsubscript{0} and S\textsubscript{2} to S\textsubscript{3} transitions. TR-MIMS has identified two types of exchangeable substrate waters, W\textsubscript{f} and W\textsubscript{s}, which are in fast and slow exchange with the bulk solvent, respectively; W\textsubscript{s} has been proposed to be a μ-oxo bridge between the Ca and Mn ion and W\textsubscript{f} as a terminal ligand coordinated to Mn,\textsuperscript{41,43} although these assignments remain unclear.\textsuperscript{44} There are additional water molecules that form an extensive hydrogen (H)-bonded network around the Mn\textsubscript{4}Ca-oxo cluster that are positioned by amino acids that interact with the μ-oxo bridges or water ligands of the cluster, including the D1-N87, D1-S169, D1-D61, CP43-R357 and D1-H337 residues in cyanobacterial PSII.\textsuperscript{2,4,5}

Although high-resolution X-ray crystallography, EXAFS and theoretical studies have provided models for the catalytic Mn\textsubscript{4}Ca-oxo cluster, the mechanism of delivery and binding of substrate water, participation of the protein environment in substrate activation and the structure of the higher S\textsubscript{3} and S\textsubscript{4} intermediates remain heavily debated. This is important as the OEC is considered to be a promising blueprint for the development of artificial catalysts for water splitting that can generate clean and renewable energy from sunlight.\textsuperscript{45-48} Currently, there is intense interest in determining the mechanism for the delivery of the substrate (H\textsubscript{2}O) and products (H\textsuperscript{+} and O\textsubscript{2}) to and from the Mn\textsubscript{4}Ca-oxo cluster in the OEC during water oxidation.\textsuperscript{49,50} Based on computational analyses of the X-ray crystal structures, there are three putative channels that are suggested to be associated with the OEC: the “narrow”, “broad” and “large” channels.\textsuperscript{50} The narrow and broad channels are proximal to the Mn4 ion, while the large channel is close to the Ca\textsuperscript{2+} ion in the Mn\textsubscript{4}Ca-oxo cluster. The barrier for the entry of water molecules in the narrow channel is suggested to be lower than that of the broad channel\textsuperscript{50} and molecular dynamics (MD) simulations have suggested that there may be strict control of accessibility and ordered substrate binding at the active site that is critical in regulating the complex chemistry of water oxidation.\textsuperscript{51,52}

Current proposals suggest that the S\textsubscript{2} to S\textsubscript{3} state transition of the OEC involves the binding of a water ligand at the Mn\textsubscript{4}Ca-oxo cluster with the oxidation of a Mn ion.\textsuperscript{37} However, there is considerable debate on the origin and binding mode of the water molecule. There are primarily two theoretical models proposed for the delivery of water in the S\textsubscript{2} to S\textsubscript{3} transition.\textsuperscript{37} In the first model, a water molecule, WX, is delivered through the narrow channel and binds to the dangler Mn4 ion through a carousel mechanism. In the second model, WX is delivered through the large channel that is proximal to the Ca\textsuperscript{2+} ion and binds to the Mn1 ion through a pivot mechanism. However, recent cryo-electron microscopy studies have shown that the “large” channel is not conserved in PSII from \textit{Synechocystis} sp. PCC 6803.\textsuperscript{53} There is an urgent need for spectroscopic data on the function of the channels and the coordination environment of the Mn ions in order to determine the precise pathway for water delivery in the OEC. PSII is a unique case where the substrate and solvent molecules are identical and, therefore, it has been a substantial challenge to differentiate between them while probing the mechanism of substrate delivery and binding in the OEC.

There are two experimental approaches that have previously been employed to investigate the delivery of the substrate: (i) to probe the water binding sites by studying the indirect effects of the site-directed mutagenesis of amino acid
residues and (ii) to employ small molecule analogs, such as ammonia, hydroxylamine and methanol, to probe access to the Mn$_4$Ca-oxo cluster in the OEC.$^{54-62}$ However, there have been few attempts to interrogate the high-resolution electronic and geometric structure of the binding of small molecule analogs associated with the various channels of site-directed variants of cyanobacterial PSII.$^{57}$ This is important as elucidation of the mechanism of water oxidation requires precise knowledge of how, when and where substrate waters bind at the Mn$_4$Ca-oxo cluster during the S-state cycle.

The X-ray crystal structures reveal that the asparagine-87 residue in the D1 polypeptide, D1-N87, is located in the "narrow" channel and is proximal to serine, arginine and aspartic acid residues (D1-S169, CP43-R357 and D1-D61, respectively) in PSII from *Thermosynechococcus vulcanus*.$^{4,50}$ The D1-N87 residue has been suggested to be involved in the delivery of water molecules, as well as proton transport in the OEC.$^{50,63}$ Moreover, D1-N87 indirectly interacts with the water molecule, WX, and is likely hydrogen (H)-bonded to the D1-S169 residue that was implicated in substrate binding in the OEC.$^{64,65}$ It is interesting that, despite the highly-conserved sequence of the OEC across species, D1-N87 in cyanobacteria is replaced by an alanine, D1-A87, in PSII from higher plants.$^{50,66}$ It has been suggested that an important consequence of the replacement of D1-N87 by alanine is that the shape and flexibility of the narrow channel is wider in higher plants, while also removing a H-bonding residue in it.$^{50}$ Some of us have previously observed that the D1-N87A variant of *Synechocystis* PCC 6803 shows comparable S-state cycling efficiency to wild-type (WT) cyanobacterial and spinach PSII.$^{67}$ However, it displays altered chloride-binding properties and pH dependence that mimic those in spinach PSII.

Based on the location and H-bonding pattern of the D1-N87 residue, it is possible that it is also involved in the delivery of substrate water at the Mn$_4$Ca-oxo cluster in the S$_2$ to S$_3$ transition. More specifically, D1-N87 could regulate the size and selectivity of the putative "narrow" channel. This is important as it is plausible that this is the only channel available for water delivery and its narrow path prevents access of larger molecules that could potentially react with the OEC. Additionally, D1-N87 could participate in maintaining the well-defined H-bonding network of water molecules in and around the OEC, which regulates the entry and binding of water ligands. Previous studies involving the binding of small molecule substrate analogs in the OEC have indicated that although methanol competes with the binding of water, its binding does not inhibit oxygen evolution. More recently, Britt and coworkers have demonstrated that isotopelabeled methanol can be used as a substrate analog to probe the binding of substrate molecules in the OEC. Using electron-spin-echo envelope modulation (ESEEM), hyperfine sublevel correlation (HYSCORE) and electron nuclear double resonance (ENDOR) spectroscopy of CD$_3$OH and $^{13}$CH$_3$OH, these studies probed the binding of methanol through the measurement of electron–nuclear hyperfine couplings of the $^2$H and $^{13}$C atom(s) with the paramagnetic Mn$_4$Ca-oxo cluster in the S$_2$ state of spinach PSII.$^{58,59}$ In particular, the use of $^{13}$C-methanol offered a selective probe of the location of the methyl group that allowed for the evaluation of possible methanol binding sites in spinach PSII.

In the present study, using two-dimensional (2D) hyperfine sublevel correlation (HYSCORE) spectroscopy, we present direct evidence of the binding of $^{13}$C-methanol to the catalytic Mn$_4$Ca-oxo cluster in the S$_2$ state of the OEC of D1-
N87A PSII from *Synechocystis* sp. PCC 6803. 2D HYSCORE spectroscopy is ideally suited to probe the binding of small molecule analogs as the hyperfine interactions of magnetic nuclei with the unpaired electron spin in the S2 state are detected in 2D frequency space, which dramatically improves the spectral resolution. Moreover, the nuclear frequencies are correlated in the two dimensions, which crucially simplifies the analysis of the experimental spectra. In conjunction with HYSCORE spectroscopy, we also employ QM/MM and density functional theory (DFT) methods to model the possible binding sites of methanol and identify the most likely binding site by obtaining a best match of the experimental and calculated $^{13}$C hyperfine couplings in the S2 state of D1-N87A PSII.

**Results and discussion**

**Pulsed EPR spectroscopy of $^{13}$C-methanol-treated D1-N87A PSII**

The S2 state of the OEC of PSII from higher plants and cyanobacteria can be photo-accumulated by steady-state illumination at cryogenic temperatures (180–200 K), which induces the one-electron oxidation of the S1 to the S2 state. We and others have demonstrated that the S2 state displays distinct low- and high-spin isomers with $g \approx 2.0$ ‘multiline’ and $g > 4.0$ EPR signals, respectively. Shown in Fig. 1SA and B† are the EPR spectra of the S2 state of wild-type (WT) and D1-N87A PSII from *Synechocystis* sp. PCC 6803 treated with 5% (v/v) $^{13}$C-methanol. The S2 state multiline EPR spectrum is centered at a $g$ value of ~2.0 with an overall spectral width of 200 mT and contains 12–14 hyperfine peaks that are characteristic of the low-spin isomer of the S2 state. The multiline signal has been shown to arise from the electron–nuclear hyperfine interactions of the effective electron spin ($S = 1/2$) with the four equivalents of $^{55}$Mn nuclear spins ($I = 5/2$) of the Mn$_4$Ca-oxo cluster in the OEC. The spectra are in agreement with previously published multiline signals of the S2 state.

In principle, the binding of $^{13}$C-methanol in the OEC should lead to additional splittings in the spectrum from hyperfine interactions of the $^{13}$C nuclear spin(s) ($I = 1/2$) with the paramagnetic Mn$_4$Ca-oxo cluster in the S2 state. However, the $^{13}$C hyperfine interactions are much weaker than the $^{55}$Mn couplings in the OEC and are masked by the inhomogeneous line width of the multiline peaks. Therefore, in the present study, we probe the $^{13}$C hyperfine couplings of $^{13}$C-methanol-treated PSII by 2D HYSCORE spectroscopy, which has the ability to resolve the weak hyperfine interactions of the $^{13}$C nuclei that are coupled to the unpaired electron spin in the S2 state.

Shown in Fig. 2A and B are the experimental and simulated $^{13}$C HYSCORE spectra of the S2 state of D1-N87A PSII from *Synechocystis* sp. PCC 6803 treated with 5% (v/v) $^{13}$C-methanol. As can be seen in Fig. 2A, we observe a pair of off-diagonal cross-peaks, C1, at (5.4, 2.1) and (2.1, 5.4) MHz in the (+,+), quadrant of the HYSCORE spectrum. The cross-peaks are centered at the $^{13}$C Zeeman frequency of 3.6 MHz (at a magnetic field of 335 mT) and arise from the hyperfine interactions of the $^{13}$C atom (nuclear spin, $I = 1/2$) of $^{13}$CH$_3$OH that is bound to the OEC in the S2 state. The separation between the pair of cross-peaks C1 is ~3.5 MHz, which is proportional to the isotropic hyperfine coupling, $A_{iso}$, of the $^{13}$C atom of bound methanol.

We performed numerical simulations of the experimental spectrum (Fig. 2B) to obtain a quantitative measure of the isotropic, $A_{iso}$, and anisotropic, $T$,
hyperfine interactions and rhombicity parameter, δ (Table 1). As can be seen in Fig. 2A and B, there is excellent agreement between the experimental and simulated line shapes of the cross-peaks, C^I. The value of the A_{iso} coupling of 3.63 ± 0.15 MHz that was obtained from the numerical simulations (Table 1) is in agreement with the qualitative estimate predicted from the separation of the cross-peaks. The anisotropic hyperfine coupling, T, of 1.65 ± 0.11 MHz is similar in magnitude to that of the protons of a water-derived ligand coordinated to the Mn4 ion.39 Interestingly, the cross-peaks display deviations from the anti-diagonal of the spectrum, shown as a dashed red line in Fig. 2B. It has previously been noted that such cross-peak distortions in HYSCORE spectroscopy could originate from a distribution of hyperfine parameters or strain in orientationally-disordered protein samples or frozen solutions, where the hyperfine strain can be modeled using a distribution function. In order to account for the hyperfine strain observed in C^I, we employed a weighted Gaussian-type function to model the distorted line shape by assigning the center of distribution and the full-width at half maximum (FWHM) in the simulations (standard deviation, σ, of 0.3 MHz).

Additionally, the experimental spectrum in Fig. 2A also reveals a cross-peak, C^{II}, on the diagonal which arises from very weak hyperfine couplings (A_{iso} < 0.1 MHz).

Table 1  Isotopic and anisotropic hyperfine parameters obtained from numerical simulations of the 2D 13C HYSCORE spectrum of the S^2 state of the OEC of the 13C-methanol bound D1-N87A variant of PSII from Synechocystis sp. PCC 6803. The hyperfine coupling constants are in units of MHz

Fig. 2  Contour-plot representation of the (+,+ ) quadrant of the (A) experimental and (B) overlay of the numerically simulated (pink) and experimental (purple) 2D 13C HYSCORE spectrum of the 13C-methanol bound S^2 state of the OEC of the D1-N87A variant of PSII from Synechocystis sp. PCC 6803. The spectrum was acquired at a magnetic field of 335.0 mT and temperature of 5 K. The dashed black and red lines represent the diagonal (defined by \( \nu_1 = \nu_2 \)) and anti-diagonal (defined by \(|\nu_1 \pm \nu_2| = 2 \times^{13}C_\rho \), where \(^{13}C_\rho \) is the carbon nuclear Larmor frequency), respectively.
MHz) of the effective electron spin \( S = 1/2 \) with ambient non-bonded \(^{13}\)C nuclei that are not directly coordinated to the Mn ions of the Mn\(_4\)Ca-oxo cluster in the S\(_2\) state.\(^{58,59}\) Therefore, \(^{14}\)N was not included in the numerical simulations in Fig. 2B. It is important to note that both of the cross-peaks, C\(_1\) and C\(_{11}\), were absent in the S\(_2\) state of untreated D1-N87A PSII (Fig. 3SA and B\(^\ddagger\)) and \(^{13}\)C-methanol-treated WT PSII from \textit{Synechocystis} sp. PCC 6803 (Fig. 4S\(^\ddagger\)), while C\(_1\) was not observed in the S\(_2\) state of \(^{13}\)C-methanol-treated PSII from spinach (spectrum not shown).

In order to assess the effects of methanol binding on the primary and secondary sphere of ligands to the Mn\(_4\)Ca-oxo cluster in the S\(_2\) state, we examined the \(^{14}\)N hyperfine interactions of \(^{13}\)C-methanol bound D1-N87A PSII. Shown in Fig. 2SA and B\(^\ddagger\) are the experimental and simulated 2D \(^{14}\)NHYSCORE spectra of the \(^{13}\)C-methanol bound S\(_2\) state of D1-N87A PSII. The \(^{14}\)N hyperfine and quadrupolar couplings in Table 1S\(^\ddagger\) indicate that the hyperfine couplings of the nitrogen atoms are identical to those observed in the S\(_2\) state of untreated WT PSII,\(^9,10,72\) indicating that magnetic interactions with the D1-H332 and CP43-R357 residues remain unchanged in the S\(_2\) state of \(^{13}\)C-methanol bound D1-N87A PSII.

QM/MM and DFT studies of methanol binding in the oxygen-evolving complex

We obtained \(^{13}\)C \( A_{\text{iso}} \) couplings of 3.63 ± 0.15 MHz and <0.1 MHz from the 2D HYSCORE spectra of the \(^{13}\)C-methanol bound S\(_2\) state of D1-N87A PSII. While the \( A_{\text{iso}} \) coupling of <0.1 MHz can be attributed to non-bonded \(^{13}\)C nuclei, the larger \(^{13}\)C \( A_{\text{iso}} \) of 3.63 ± 0.15 MHz suggests that methanol is directly coordinated to a paramagnetic Mn ion in the S\(_2\) state of the OEC of D1-N87A PSII.\(^58\) As evidenced in previous studies, direct structural assignment of the specific binding sites in the OEC based solely on the measured hyperfine parameters is limited in scope. However, it is possible to interpret the EPR parameters in conjunction with quantum mechanical models to gain insight into the binding of ligands in the OEC.\(^73-75\)

Since the binding of methanol increases the energy separation between the S\(_2\) state spin isomers,\(^54,76-78\) stabilizing the \( S = 1/2 \) ground spin state of the S\(_2\) state, we used QM/MM methods to optimize structural models of the low-spin \( g \sim 2.0 \) open cubane conformer of the Mn\(_4\)Ca-oxo cluster to evaluate the possibility of a methoxy group or methanol interacting with the Mn\(_4\)(\textit{iv}) or Mn1(\textit{iii}) ion. The QM/MM studies yielded three plausible models in which methanol binds to the cluster in the protonated or deprotonated methoxy form (Fig. 3A–C). In the first model, Mn4-W1, a methoxy group displaces the water-derived ligand W1 that is coordinated to the Mn\(_4\)(\textit{iv}) ion in the low-spin \( g \sim 2.0 \) isomer of the S\(_2\) state, binding at a distance of 2.1 Å (Fig. 3A). In this case, the methoxy group is accepting a hydrogen bond from the protonated D1-D61 residue. The methyl group is between the backbone of the D1-S169 residue and the water molecule, W9, where one of the methyl hydrogen atoms donates a short (1.5 Å) hydrogen bond to W9. In the second model, Mn4-W2, a methoxide group displaces the water-derived ligand W2, binding to Mn\(_4\)(\textit{iv}) at a distance of 1.8 Å, accepting a hydrogen bond from the water molecule, W5 (Fig. 3B). The methyl group is located less than 4 Å from the D1-V185 residue, where it is in contact with the rigid side chain of valine and one of the methyl hydrogen atoms donates a hydrogen bond (2.1 Å) to the water molecule, W8.
Fig. 3  QM/MM models of methanol binding at a Mn ion of the Mn₄Ca-oxo cluster in the S₂ state. The (A) Mn4-W1 model where a methoxy group replaces the water ligand W1 at the Mn4(IV) ion, (B) Mn4-W2 model where a methoxy group replaces the water ligand W2 at the Mn4(IV) ion and (C) Mn1-methanol model with methanol binding at the Mn1(III) ion. The manganese, calcium, carbon, nitrogen, oxygen and hydrogen atoms are shown in purple, yellow, grey, blue, red and white color, respectively.
In contrast to the two Mn4 models, methanol displaces D1-E189 ligand in the third model, Mn1-MeOH, binding to the Mn1(III) ion and donating a short (1.4 Å) hydrogen bond to the displaced D1-E189-Oe2 atom (Fig. 3C). The Oe2 atom in turn displaces Oe1 to bind to the calcium ion of the OEC. In this case, Oe1 is no longer coordinated to a metal ion, and instead inserts itself between the waters, W3 and W7, disrupting the H-bonded water tetramer in the OEC. The methyl group of the methanol points towards the large channel and does not appear to form any notable interactions. We observed that the geometric parameters of the Mn and Ca ions of the Mn3Ca-oxo cluster, as well as the amino acid ligands of all three QM/MM models, are consistent with the X-ray structures of PSII. It is important to note that while methanol can readily access the Mn4 ion in the Mn4-W1 and Mn4-W2 models, it has very limited access to the Mn1 ion due to steric limitations of the site. Previous studies by Britt and coworkers also considered the binding of methanol either in µ-oxido positions replacing either the O42⁻ or O52⁻ ion or the W3 water coordinated at the Ca²⁺ ion. We did not consider a bridging µ-oxido as we do not observe large alterations in the 14N hyperfine couplings and effective 55Mn couplings. Moreover, the large 13C Aiso value of 3.63 ± 0.15 MHz indicates that the methanol is directly coordinated to a paramagnetic Mn, which limits the possibility of its binding at the Ca²⁺ ion. However, it is possible that the Aiso of <0.1 MHz obtained from the experimental data represents the binding of a second methanol/methoxy group at the Ca²⁺ ion. As we and others have previously demonstrated, the best way to validate the QM/MM structural models of the methanol-bound S₂ state is by the prediction of the 13C hyperfine interactions.

After validating our predictions of 13C hyperfine couplings using broken-symmetry density functional theory (BS-DFT) methods to reproduce the hyperfine interactions of select computational models described by Retegan and Pantazis, we calculated the 13C hyperfine couplings for the three QM/MM models described above (Table 2) for comparison with the experimental hyperfine couplings shown in Table 1. We found that the calculated isotropic and anisotropic hyperfine couplings of Mn4-W2 are consistent with the results of the HYSCORE studies. As can be seen in Table 2, the BS-DFT calculations of the model with a methoxy group coordinated at the W2 position of the Mn4(IV) ion yielded 13C isotropic and anisotropic hyperfine couplings of 3.23–3.37 MHz and 1.89–1.90 MHz, respectively, which are close to the experimental 13C Aiso and T values of 3.63 ± 0.15 and 1.65 ± 0.11 MHz in Table 1, respectively. Moreover, the 13C hyperfine couplings of the Mn4-W2 model are also in the range of the previous

Table 2 Normalized 13C-hyperfine constants for methanol/methoxy binding in the OEC that were calculated using a TPSSh functional with the EPR-II or ZORA/TZVP basis set. The hyperfine coupling constants are in units of MHz.
model W2-1d in a study where the authors had selected twenty representative structures that covered a range of possibilities with respect to the interaction of methanol with the OEC. These models included structures where methanol was either protonated or deprotonated when binding as a first-sphere ligand. In general, it was found that the $^{13}$C $A_{\text{iso}}$ and $T$ values of methoxy binding were dramatically larger (5.73–4.06 MHz and 1.53–2.96 MHz for $A_{\text{iso}}$ and $T$, respectively) than the corresponding values for methanol binding, which is consistent with the larger couplings observed in the present study.

It is interesting that the results obtained with $^{13}$C-methanol binding in the S$_2$ state of D1-N87A PSII in this study are different from those of spinach PSII. While the HYSCORE spectra of the $^{13}$C-methanol bound S$_2$ state of D1-N87A PSII yield off-diagonal cross-peaks with a $^{13}$CA$_{\text{iso}}$ coupling of 3.63 ± 0.15 MHz, previous $^{13}$C-methanol binding studies in spinach PSII displayed weak $^{13}$C couplings that were not resolved by X-band HYSCORE spectroscopy. Further Q-band electron nuclear double resonance (ENDOR) measurements of the samples yielded $A_{\text{iso}}$ and $T$ values of 0.05 ± 0.02 MHz and 0.27 ± 0.05 MHz, respectively. Based on the nearly negligible $^{13}$C $A_{\text{iso}}$ coupling, it was inferred that methanol was not binding along the Jahn–Teller axis of the Mn$_1$(III) ion and the small anisotropic coupling $T$ suggested that the methyl group was not part of a ligand coordinated at a Mn ion in the S$_2$ state. Isosurface plots using projection factors relevant for the low-spin S$_2$ state indicated that methanol could replace the W3 water ligand coordinated at the Ca$^{2+}$ ion of the cluster in spinach PSII. Further detailed analyses of the $^{13}$C hyperfine interaction data from a series of quantum chemical models that included the explicit binding of methanol at different sites indicated that it was not a direct ligand, but was likely situated at the end-point of a water channel associated with the O$_{42}^{2−}$ bridge in the OEC of spinach PSII. This observation was supported by FTIR difference and time-resolved IR and proton matrix ENDOR spectroscopies.

The $^{13}$CA$_{\text{iso}}$ value of 3.63 ± 0.15 MHz in the $^{13}$C-methanol bound S$_2$ state of D1-N87A PSII is roughly comparable to the signals that were obtained from the binding of $^{13}$C methanol to Mn(III)Mn(IV)salpn (where, salpn = $N$,N$'$-bis(3,5-dichlorosalicylidene)-1,3-diamino-2-hydroxypropane). The cross-peaks from methanol-bound Mn(III)Mn(IV)salpn were numerically simulated by using moderate $A_{\text{iso}}$ and $T$ couplings of 0.65 ± 0.05 MHz and 1.25 ± 0.05 MHz, respectively. In the case of Mn(III)Mn(IV)salpn, the degree of curvature of the correlation ridge was taken to be diagnostic of a large anisotropic hyperfine interaction, where $T > A_{\text{iso}}$. However, we observed an opposite trend with $^{13}$C-methanol binding, where the $A_{\text{iso}}$ coupling of 3.63 ± 0.15 MHz is larger than the anisotropic component of 1.65 ± 0.11 MHz.

Previous $^{13}$C ENDOR measurements of the S$_2$ state in which either the alanine carboxylate carbons or all the carbon atoms were $^{13}$C-labeled showed $A_{\text{iso}}$ couplings of 1.2 MHz and 1.2–2.0 MHz for the D1 C-terminus alanine ligand and uniformly $^{13}$C-labeled ligands, respectively. Subsequent studies using BS-DFT calculations suggested that symmetrically bridging carboxylate groups generally provided larger anisotropic hyperfine couplings and rhombicities than terminal or Mn–Ca bridging ligands. The interpretation of the ENDOR results and computational models for the BS-DFT calculations originated prior to the high-resolution X-ray crystal structure of PSII. Most recently, calculations based on models derived from the 1.9 Å resolution X-ray structure indicated multiple $A_{\text{iso}}$.
couplings in the range of 1.3–4.3 MHz for the carboxylate ligands in the S\textsubscript{2} state of the OEC.\textsuperscript{83}

By combining previous pulsed EPR and computational analyses of methanol\textsuperscript{58,63} and ammonia binding,\textsuperscript{57,61,84–86} it was suggested that there is a unique channel active in the delivery of substrate analogues to the OEC. In the literature, this channel is referred to as the “narrow” channel,\textsuperscript{87} “E, F” channel,\textsuperscript{88} “channel 2”,\textsuperscript{89} “O4” or “Path 3” channel.\textsuperscript{90} Ho and Styring had initially suggested that this channel would be the most permeable to methanol.\textsuperscript{87} Molecular dynamics simulations by Bruce and coworkers demonstrated that this channel connects the OEC directly with the luminal surface of PSII at the cavity formed by the extrinsic PsbO and PsbU proteins, and it has the lowest free energy barrier for water permeation (peak activation energy ca. 9 kcal mol\textsuperscript{-1}) than all other channels.\textsuperscript{89} Moreover, recent experiments demonstrated that NH\textsubscript{3} binds to the Mn4 ion in the S\textsubscript{2} state of the OEC.\textsuperscript{57,84–86} Although the conformation of the cluster is fundamentally different when NH\textsubscript{3} and MeOH bind to the OEC, it appears that both analogs act as a direct ligand to the Mn4 ion. The narrow channel that is suggested as the methanol access pathway could be the same one that delivers ammonia to the Mn4 ion, supporting the notion that this is the only directly solvent-accessible manganese site of the OEC.\textsuperscript{63} Additionally, studies of the S\textsubscript{2} → S\textsubscript{3} transition and proposals for water binding in the OEC (in both the carousel and pivot mechanism),\textsuperscript{37} have suggested that Mn4 is the only directly accessible Mn ion of the cluster and that substrate inclusion to the OEC occurs through initial binding at this site. This is in agreement with the present study, where computational analysis of the \textsuperscript{13}C HYSCORE experimental data indicates that a deprotonated methoxy group binds at the W2 position at the Mn4(IV) ion in the S\textsubscript{2} state of D1-N87A PSII. Further studies are in progress to understand the mechanistic implications for the water oxidation reaction in the OEC.

Previous comparisons of the primary sequence of the D1 polypeptide of cyanobacteria and spinach revealed that the substitution of the D1-N87 residue by an alanine in spinach allows for the binding of methanol in the OEC. This offered a structure-based proposal for the species-dependent response to methanol. Moreover, it was found that the D1-N87A mutation made chloride binding weaker and the dissociation of chloride more facile, suggesting that the replacement of D1-N87 by alanine alters the access of small molecules and ions from the lumen to the OEC.\textsuperscript{67} Subsequently, detailed computational analyses by Pantazis and coworkers converged upon an atomistic model that was consistent with experimental observations of methanol binding in spinach PSII.\textsuperscript{63} However, it did not directly explain why methanol binding was less pronounced in cyanobacteria. There were no species-dependent substitutions for any of the amino acid residues in the previous computational models, and hence it is improbable that fundamentally different access modes exist between species. Hence, the model must have been equally valid for both cyanobacteria and higher plants, if methanol can reach this site and adopt these positions in all organisms. The narrow channel was suggested to be the structural origin of the species-dependent response to methanol and it is proposed to act as the substrate delivery channel. Within the context of the present work, the above \textsuperscript{13}C HYSCORE, QM/MM and DFT analyses establish that the substitution of the D1-N87 residue by alanine leads to the delivery and binding of methanol in the S\textsubscript{2} state of cyanobacterial PSII.
Conclusions

In summary, the use of $^{13}$C HYSCORE spectroscopy in conjunction with QM/MM and DFT provides evidence that $^{13}$C-methanol is coordinated to the OEC in the S$_2$ state of D1-N87A PSII from Synechocystis sp. PCC 6803. Previous studies have shown that the D1-N87 residue in cyanobacterial PSII is required for the efficient S-state cycling of the OEC and the replacement of D1-N87 by an alanine residue alters the Cl$^-$/C$_0$-binding properties, such that D1-N87A PSII mimics spinach PSII. The results of the present study confirm that the size and specificity of the “narrow” channel is altered in D1-N87A PSII, allowing for the binding of deprotonated $^{13}$C-labeled methanol to the Mn$_4$ ion of the catalytic cluster, which has important implications for the mechanistic models for water oxidation in PSII.
